Abstract

Perceived intensities of sweetness and bitterness are correlated with one another and each is influenced by genetics. The extent to which these correlations share common genetic variation, however, remains unclear. In a mainly adolescent sample (n = 1901, mean age 16.2 years), including 243 monozygotic (MZ) and 452 dizygotic (DZ) twin pairs, we estimated the covariance among the perceived intensities of 4 bitter compounds (6-n-propylthiouracil (PROP), sucrose octa-acetate, quinine, caffeine) and 4 sweeteners (the weighted mean ratings of glucose, fructose, neohesperidine dihydrochalcone, aspartame) with multivariate genetic modeling. The sweetness factor was moderately correlated with sucrose octa-acetate, quinine, and caffeine (r̂p = 0.35–0.40). This was mainly due to a shared genetic factor (r̂g = 0.46–0.51) that accounted for 17–37% of the variance in the 3 bitter compounds’ ratings and 8% of the variance in general sweetness ratings. In contrast, an association between sweetness and PROP only became evident after adjusting for the TAS2R38 diplotype (r̂p increased from 0.18 to 0.32) with the PROP genetic factor accounting for 6% of variance in sweetness. These genetic associations were not inflated by scale use bias, as the cross-trait correlations for both MZ and DZ twins were weak. There was also little evidence for mediation by cognition or behavioral factors. This suggests an overlap of genetic variance between perceptions of sweetness and bitterness from a variety of stimuli, which includes PROP when considering the TAS2R38 diplotype. The most likely sources of shared variation are within genes encoding post-receptor transduction mechanisms common to the various taste G protein-coupled receptors.

Key words: IQ, personality, sweetener, taste, TAS2R38, twins

Introduction

Taste perception varies greatly among individuals. For over a decade, intensity ratings of the bitter compound 6-n-propylthiouracil (PROP) have been used to distinguish an individual’s “bitter taster status” (Hayes and Keast 2011), with those rating it as extremely bitter sometimes described as “supertasters” (Bartoshuk et al. 1994). Many studies suggested these individuals are also more sensitive
to other taste stimuli (Bartoshuk 1979; Tepper and Nurse 1997; Lucchina et al. 1998; Ly and Drewnowski 2001; Bajec and Pickering 2008; Fischer et al. 2014), whereas many others have failed to find such associations (Schifferstein and Frijters 1991; Drewnowski et al. 1997; Drewnowski et al. 1998; Keast and Roper 2007; Lim et al. 2008). Therefore, whether individual differences in ratings of a single compound can generalize to other taste stimuli has been questioned and, furthermore, whether there are pan-quality overarching individual differences remains unclear (Lim et al. 2008; Hayes and Keast 2011; Fischer et al. 2014).

Most of the perceptual variability in PROP is due to genetic variation within the bitter taste receptor TAS2R38 (Drayna et al. 2003; Bufe et al. 2005; Reed et al. 2010). Genetic variation in TAS2R38 does not appear to be associated with perceived intensity of other taste stimuli (e.g., quinine, and sucrose) (Hayes et al. 2008), but some evidence shows that the TAS2R38 diplotype may modify the association between PROP and other tastes (Fischer et al. 2014). In addition, the PROP response has been shown to be less predictive of overall perceived taste intensity than are collective ratings of sucrose, sodium chloride, citric acid, and quinine (Lim et al. 2008), suggesting that PROP ratings are not a sole predictor for overall taste perception. Rather, a more complex association across multiple taste classes, such as general differences in the “gain” of the taste system, appears to be at play.

A parallel body of work reveals that genetics plays a significant role in the perception of different taste qualities, accounting for over 30% of the variance in sweetness, sourness, and bitterness (Hansen et al. 2006; Wise et al. 2007; Knaapila et al. 2012; Hwang et al. 2015). Our previous studies identified a shared genetic pathway for taste perception across different bitter compounds, excluding PROP (Hansen et al. 2006), and more recently a common genetic factor for the perception of both sugars and non-caloric sweeteners (Hwang et al. 2015). Although the perception of sweetness has been weakly-to-moderately correlated with bitterness (Lim et al. 2008; Knaapila et al. 2012; Fischer et al. 2014), whether this association is due to shared genes has not been determined in humans. In addition, there is evidence that non-receptor based factors may contribute to the correlation between sweet and bitter taste perceptions. For example, prosocial (e.g., agreeableness) and antisocial (e.g., psychopathy) personalities are associated with elevated sweet and bitter taste preferences, respectively (Meier et al. 2012; Sagigolou and Greitemeyer 2016). Further, other concerns, such as psychometric properties of scale use (e.g., a tendency to rate at one side of the scale [Jewell and McCourt 2000]) and even intelligence [e.g., higher IQ is associated with less extreme rating styles (Light et al. 1965)] need to be raised when studying weak sensory associations.

The present study investigated the sources of association between multiple taste qualities using a large adolescent and young adult twin sample. Genetic covariances between perceived intensity of 4 sweet (glucose, fructose, neohesperidine dihydrochalcone [NHDC], and aspartame) and 4 bitter solutions (PROP, SOA, quinine HCl [quinine], and caffeine) were estimated using multivariate genetic modeling. In addition, this study examined the impact of the TAS2R38 diplotype on the genetic covariances, and potential confounding effects of scale use bias, general cognitive ability, and behavioral factors.

Materials and methods

Participants

Participants were adolescent and young adult Caucasian twins and their singleton siblings from the Brisbane Adolescent Twin Study (Wright and Martin 2004), also referred to as the Brisbane Longitudinal Twin Study (BLTS). They were originally recruited for a study on melanoma (Zhu et al. 2007), a common form of cancer among light-skinned people. The taste data reported here were collected between August 2002 and July 2014. The sample comprised 243 monoozygotic (MZ) and 452 dizygotic (DZ) twin pairs, including 126 pairs with 1–2 singleton siblings, and 320 unpaired individuals (mean age of 16.2 ± 2.8 years; 1023 females, 878 males) (Supplementary Table 1). This is the same sample as used previously (Hwang et al. 2015). Zygosity was determined from genotyping (92% of same sex twin pairs) or from self-report. The Queensland Institute of Medical Research Human Ethics Committee approved the study. Written consent was obtained from both the participants and their parents (the latter not required for those 18 years and over).

Taste test

The taste test battery has been described in detail elsewhere (Hansen et al. 2006; Hwang et al. 2015). Briefly, participants rated the intensity of 5 bitter (6.0 × 10⁻⁴ M PROP, 2.0 × 10⁻⁴ M SOA, 1.81 × 10⁻⁴ M quinine, 0.05 M caffeine, and 4.99 × 10⁻⁴ M denatonium benzoate) and 4 sweet (0.60 M glucose, 0.30 M fructose, 8.0 × 10⁻⁴ M NHDC, and 1.4 × 10⁻⁴ M aspartame) solutions using a general labeled magnitude scale (gLMS) (Green et al. 1993). Mean intensity ratings from duplicate presentations for each of PROP, SOA, Quinine and Caffeine were used in all analyses. For the 4 sweet compounds, a weighted mean general sweet (gSweet) factor was used, as perceived intensity of the sweeteners is highly correlated at the genetic level (r = 0.78–0.89) and most of the variance (71% for glucose, 77% for fructose, 64% for NHDC, and 59% for aspartame) is accounted for by a common genetic factor (Hwang et al. 2015). Denatonium benzoate was not included due to the violation of the normality assumption, a criterion for twin modeling (Neale et al. 2002) (see Statistical Analyses). Statistical transformation failed to overcome this problem because of its distinct bimodal distribution (Supplementary Figure 1). In addition, the mean intensity rating for denatonium benzoate was double that of other stimuli, with the most common rating being the strongest imaginable on the scale, suggesting that the concentration may have been too high to detect variation (also known as a “ceiling effect”). The intensity rating characteristics for denatonium benzoate are summarized in Supplementary Table 2.

TAS2R38 diplotype

The genotypes for the 3 TAS2R38 SNPs (rs713598, rs1726866, and rs10246939), resulting in 3 amino acid substitutions (A49P, A262V, and V296I), were available for 92% of the sample. Genotyping was done using the Illumina 610-Quad BeadChip (n = 1254) (Reed et al. 2010) or HumanCoreExome-12 v1.0 BeadChip. The frequencies of the 3 diplotypes [PAV/PAV = 17%, PAV/AVI = 52% (including 34 participants with rare diplotypes of AAV/AVI or PAV/AAV, which were shown to have similar effects on PROP perception as the PAV/AVI diplotype [Bufe et al. 2005]), and AVI/AVI = 31%] were similar among light-skinned people. The taste data reported here were collected between August 2002 and July 2014. The sample comprised 243 monoozygotic (MZ) and 452 dizygotic (DZ) twin pairs, including 126 pairs with 1–2 singleton siblings, and 320 unpaired individuals (mean age of 16.2 ± 2.8 years; 1023 females, 878 males) (Supplementary Table 1). This is the same sample as used previously (Hwang et al. 2015). Zygosity was determined from genotyping (92% of same sex twin pairs) or from self-report. The Queensland Institute of Medical Research Human Ethics Committee approved the study. Written consent was obtained from both the participants and their parents (the latter not required for those 18 years and over).

Statistical analyses

The heritability and phenotypic correlations among the intensity scores of gSweet and the 4 bitter substances were estimated using univariate and bivariate variance components modeling. This twin method partitions the phenotypic variance or covariance into additive genetic (A), common environment (C) and unique environment (E) factors.
To estimate the covariance structure between the 5 traits, a multivariate Cholesky decomposition model (Neale and Cardon 1992) was used as a starting point. A series of models, including dropping A and C components, were tested to determine which pattern of covariance best fitted the data. For nested models, we assessed the comparative fit by calculating the difference in double the negative log-likelihood, which is distributed asymptotically as a χ². For non-nested models, the Akaike’s Information Criterion (AIC), which penalizes models for increasing complexity (Burnham and Anderson 2002), was used. The effect of the TAS2R38 diplotype on the covariance structure was tested in a partial dominant model with 1 covariate for the heterozygous effect (i.e. PAV/AVI = 1 and PAV/PAV = AVI/AVI = 0) and a second covariate for the PAV homozygous effect (i.e. PAV/PAV = 1 and AVI/AVI = PAV/AVI = 0). Consequently, the genetic variance in PROP dropped from 0.72 to 0.20 (compared with an additive or dominant model where PROP genetic variance reduced to 0.25 and 0.24, respectively). This model was used to examine the covariance structure when the TAS2R38 genetic effect on intensity ratings was removed. A second model in which the low-sensitivity tasters for PROP (30% of the genotyped sample) were excluded from the analyses was also tested.

In addition, this study investigated whether intensity ratings were associated with general cognitive ability (Verbal IQ), assessed with the Multidimensional Aptitude Battery (Jackson 1998), and personality (neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness) assessed with the NEO Five-Factor Inventory (FFI) (Costa and McCrae 1992). Both cognition and personality were assessed at age 16, which for the majority of twins were 2 years after assessment for sweet and bitter taste. Verbal IQ and personality were available for 1282 and 1277 participants, respectively (Loehlin et al. 2015). Further, to assure that the associations were estimated from taste perception and were not inflated by scale use bias, an emphasis score: 0 = neutral, 1 = somewhat, 2 = strongly was calculated by folding the 5-point Likert scale of the 60 responses from the NEO-FFI strongly agree = 5, agree = 4, neutral = 3, disagree = 2, strongly disagree = 1. We tested these scale bias scores for relation with the taste ratings, Where an association was indicated, the measure was included as a covariate in the multivariate model to examine whether the genetic architecture was changed. Lastly, cross-correlations were calculated between the intensity ratings of PROP for the first born twin with those of their co-twin’s ratings for the other 4 traits, for both MZ and DZ pairs, to examine any genetic effect on scale use rather than taste perception.

Results

Mean ratings, standard deviations, twin correlations, and heritability estimates for the perceived intensity of PROP, SOA, quinine, caffeine, and gSweet are shown in Table 1. The mean rating was lower for PROP, and the variance was slightly larger, compared with the other bitter compounds. This was due to the distinct differences in PROP response between the 3 TAS2R38 diplotype groups and 31% of the participants being low-intensity tasters who could barely detect the bitterness in PROP (Figure 1). In contrast, there was no effect of the TAS2R38 diplotype on SOA, quinine, caffeine, or gSweet. Heritability for PROP ($h^2 = 0.73$) was significantly higher than that for SOA, quinine, and caffeine ($h^2 = 0.35–0.40$), in line with prior work (Hansen et al. 2006). The mean and heritability ($h^2 = 0.36$) estimates for the gSweet factor are the same as those reported previously (Hwang et al. 2015).

Perceived intensity for gSweet was moderately correlated with those for SOA, quinine, and caffeine ($r_{xy} = 0.35–0.40$) and more weakly associated with PROP ($r_{xy} = 0.22$) (Table 1). Multivariate model-fitting showed that the common environmental components (C) could be dropped without loss of fit (Supplementary Table 4). Multivariate AE modeling identified a genetic factor (A2 factor in Figure 2) accounting for 8% of the variance in gSweet and 17–37% of the variance in SOA, quinine, and caffeine. Only 1% of the variance in gSweet was genetically shared with PROP (A1 factor in Figure 2). There was also little shared genetic variance between PROP and the other 3 bitter compounds (i.e. 1–3%, A1 in Figure 2). Further, the association between gSweet and PROP was largely due to an environmental “PROP” factor (E1), accounting for 27% of the variance in PROP and 6% in gSweet. This environmental factor also accounted for a small amount of the variance (9–12%) in SOA, quinine, and caffeine.

When the model was adjusted for the TAS2R38 diplotype (i.e. the TAS2R38 genetic effect was removed), the correlation between gSweet and PROP increased ($r_{xy} = 0.32$), as did the correlation between PROP and the other bitter compounds ($r_{xy}$ increased from 0.25–0.31 to 0.37–0.44) (Table 1). The stronger association was due to an increase in shared genetic variance with 6% of variance in gSweet now overlapping with the genetic variance for PROP (A1 in Figure 3a; $h^2$ of PROP decreased to 0.40 after adjustment). Similarly, after adjusting for TAS2R38, there was an increase in shared genetic variance for SOA, quinine, and caffeine with PROP. Notably, no increase in the environmental variance (E1) shared with PROP was found for gSweet, SOA, Caffeine, or Quinine. Adjusting for TAS2R38 reduces the absolute genetic variance in PROP, with environmental variance for PROP and the genetic and environmental variances of other tastes remaining the same (Supplementary Table 5). In addition, removing PROP low-sensitivity tasters, rather than adjusting for TAS2R38, produced a similar covariance structure, even though the sample size was reduced (Figure 3b; Supplementary Table 5c). This increase in the genetic correlations after adjustment for TAS2R38 or removal of PROP low-sensitivity tasters (Table 2) contrasts with the environmental correlations that remained the same. In terms of genetic
Further, there was little evidence of the effect of scale use bias, IQ, or personality on intensity ratings. While some weak associations were observed (Supplementary Table 8), there was no change in the covariance structure when the emphasis score, IQ, and personality were included as covariates in the multivariate model (Supplementary Table 9). In addition, scale use had no effect on the genetic estimates; the cross-trait (e.g. PROP for twin 1 with gSweet for twin 2) correlations for both MZ and DZ twins were low and of similar magnitude ($r_{MZ} = 0.0–0.10$, $r_{DZ} = 0.03–0.11$; Supplementary Table 10).

**Discussion**

This study examined whether there is heritable genetic overlap between the perception of sweetness and bitterness of 8 different compounds. Using multivariate genetic modeling, we showed that up to a quarter of the genetic variance in sweet perception is shared with at least half, or more, of the genetic variance in SOA, quinine, and caffeine. Further, after adjustment of the TAS2R38 diplotype, 15% of genetic variance in sweetness is also in common with PROP perception. These results suggest that human perceptions of sweetness and bitterness are linked through shared genes and the extent of overlap depends on the specific taste stimuli.

Confirming prior work, intensity ratings for sweetness were weakly-to-moderately associated with bitterness ratings (Lim et al. 2008; Knaapila et al. 2012; Fischer et al. 2014). Although Lim et al. (2008) only found an association between sucrose and quinine and not between sucrose and PROP, their sample size was small ($n = 83$) compared to Fischer’s and ours ($n = 1670$ and 1901, respectively). This suggests that a bigger sample size is required to detect weak associations with PROP. Our finding that the associations between
Figure 2. proteins in the oral cavity (Reed et al. 2006; Temussi 2009). Genetic factor supports the current understanding that, in humans, gSweet and SOA, quinine, and caffeine were mainly due to a shared mechanism influences general responsiveness to tastes. In that study, the ability to perceive thermally induced taste predicted higher taste responses to sweet and bitter stimuli, including PROP, as well as salty, sour, and umami taste stimuli. They eliminated the potential confounders of papillae density and gustatory afferents used in signal transduction and concluded that the overall control of gain in the orosensory system is likely centrally determined.

In addition to the perception of sweetness and bitterness, the shared genetic factors identified here could also link to the perception of umami taste, especially at the peripheral level, because a glutamate taste receptor is also a member of the Class I Taste GPCR family (Li et al. 2002; Temussi 2009). Animal studies have shown that these taste qualities (sweetness, bitterness, and umami) are encoded by common downstream transduction components that are not believed to be used by ionic taste stimuli (sourness and saltiness) (Zhang et al. 2003; Taruno et al. 2013). Future taste genetic studies involving glutamate, salts, and acids could test this hypothesis in humans and would help tease apart which common genes are involved.

To assure that the genetic overlap between sweetness and bitterness was not due to confounding factors, we tested a series of alternative hypotheses. First, we found only subtle associations between personality traits and taste ratings, in contrast to other studies (Meier et al. 2012; Sagioglou and Greitemeyer 2016). This difference between our weak personality influence and those previously observed may be due to differences in measures of taste preference rather than taste intensity in this study. Second, individuals with higher IQ rated taste solutions as less intense. There is some evidence that people with higher IQ are less likely to give extreme ratings (Light et al. 1965) due to differences in measures of taste preference rather than taste intensity. Nevertheless, neither personality traits nor IQ modifies the genetic association may be due to pleiotropic effects with shared genes influencing both taste perception and the development of intelligence. Nevertheless, neither personality traits nor IQ modifies the genetic architecture between sweetness and bitterness. Third, the emphasis scores were not associated with any taste ratings, so an individual’s response style is not likely a concern. Lastly, scale use style is not

n = 1229, n = 1756. TAS2R38 diplotype was tested in a partial dominant model.

gSweet and SOA, quinine, and caffeine were mainly due to a shared genetic factor supporting the current understanding that, in humans, the perception of both sweetness and bitterness is mediated via G protein-coupled receptors (GPCR) and other shared transduction proteins in the oral cavity (Reed et al. 2006; Temussi 2009). Genetic variation in these taste genes has been shown to link to individual differences in the perception of both sweetness (Fushan et al. 2009; Fushan et al. 2010) and bitterness (Reed et al. 2010; Ledda et al. 2014). Evidence from animal models also shows that knocking out common genes in their downstream signaling pathways, including genes that encode the G-protein alpha-gustducin, Ggamma13, the lipid enzyme phospholipase C beta2, and transient receptor potential ion channel TRPM5, leads to a reduced response to both sweet and bitter tastes (Taruno et al. 2013; Wong et al. 1996; Zhang et al. 2003).

Our prior work showed that the perception of PROP was weakly associated with the perception of other bitter compounds at the genetic level (Hansen et al. 2006). Here, using a greatly expanded sample, this study confirmed this lack of strong association, but also identified, after adjusting for the TAS2R38 diplotype, a shared genetic factor accounting for some of the genetic variance in the perception of PROP as along with other bitter and sweet tastes. This finding supports the 2-locus model (Olson et al. 1989) of the perception of TAS2R38 associated bitter compounds [i.e. PROP and its structurally related chemical propylthiocarboamide (Bufo et al. 2005)], with 1 locus controlling compound-specific tasting and the other locus controlling general taste responsiveness. This shared genetic factor (A1 factor in Figure 3) may correspond to a shared pathway at the peripheral level because the perception of PROP is believed to go through the same GPCR-based signaling elements as other bitter and sweet tastes (Margolskee 2002; Chaudhari and Roper 2010). Alternatively, shared genetic variation could also involve a shared pathway at the central neural level, supporting the hypothesis (Green and George 2004) that a central nervous system mechanism influences general responsiveness to tastes. In that study, the ability to perceive thermally induced taste predicted higher taste.
influenced by genetics and did not inflate or deflate the estimates of heritability or genetic covariances. The last test supports that a gLMS can be a valid instrument to study taste genetics. These 4 tests of alternative hypotheses allow us to conclude more strongly that the genetic correlation between sweetness and bitterness results from true correlates of taste perception and that these estimates of genetic covariances are valid rather than an artifact of scale use.

There are some limitations of this study. First, partitioning trait variance using Cholesky decomposition is restricted by the trait order in the model, with only the last trait in the model including a trait specific factor. For all other traits, the trait-specific variance is pushed to a group factor(s), which can, therefore, elevate covariances between traits. We tested these models in different orders, however, and obtained similar results. Second, although adjusting for the TAS2R38 diplotype increased the shared genetic variance between PROP and other taste stimuli, the increase was small and the confidence intervals overlapped [e.g. gSweet increased from 3% (confidence intervals: 0 and 9%) to 1.5% (confidence intervals: 5 and 30%)]. Future studies with larger samples could provide more distinct results. Lastly, whether there is a common genetic pathway for the overall taste perception cannot be answered from this study. Although we showed a genetic factor for the perception of both sweet and bitter tastes, even including PROP, it might simply be a specific taste transduction factor that does not also account for the perception of umami, sourness, and saltiness.

In conclusion, this study examined the associations among perceived intensities of 4 bitter compounds—PROP, SOA, quinine, and caffeine—and an average sweet factor from 4 sweeteners, and modeling results identified 2 latent genetic factors suggesting 2 shared genetic pathways. We speculate that there are genes responsible for the recognition of a GPCR-taste signal or a general taste signal. Genetic covariation of downstream signaling elements could involve peripheral and/or central mechanisms, including genes encoding molecules that transduce information from the taste receptors to the nerves and neural elements in the gustatory brain circuits. Future genome-wide association analysis in humans could identify common genes across different taste modalities, which have implications for understanding the molecular mechanism of GPCR-transduced taste perception as well as the taste-based metabolic signals from the gastrointestinal tract, pancreas, liver, thyroid, and elsewhere.
