Figure S1a-b: Quantile-quantile (QQ) plot based on (a) λ_{GC} corrected input files, and (b) based on uncorrected input files

a.

b.

Figure S2a-i. Manhattan plots of the individual samples in the discovery meta-analysis (lambda corrected)

The y-axes show the strength of association ($-\log_{10}(P)$) and the x-axes the chromosomal position. The blue line indicates suggestive significance level (P-values $< 10^{-5}$) and the red line indicates genome-wide significance level (P-values $< 5 \times 10^{-8}$).

a. Avon Longitudinal Study of Parents and Children (ALSPAC)

b. Brisbane Longitudinal Twin Study (BLTS)

c. Finnish Twin Cohort (FinnTwin12 & FinnTwin16)

d. Hospital Universitari Vall d'Hebron – Barcelona (HUVH-Barcelona)

e. Netherlands Twin Register (NTR)

f. Queensland Institute of Medical Research Berghofer adults (QIMR Berghofer adults)

g. Tracking Adolescents' Individual Lives Survey (TRAILS)

h. Utrecht

i. Genetics of Substance Dependence - European American (Yale-Penn)

Figure S3a-i. Quantile-quantile plots of the individual samples in the discovery meta-analysis (lambda corrected).

The plots compare observed p-values with p-values expected from a normal distribution.

a. Avon Longitudinal Study of Parents and Children (ALSPAC) lambda=.96

b. Brisbane Longitudinal Twin Study (BLTS) $\lambda=1.08$

c. Finnish Twin Cohort (FinnTwin12 & FinnTwin16) $\lambda=1.17$

d. Hospital Universitari Vall d'Hebron – Barcelona (HUVH-Barcelona) $\lambda=1.11$

e. Netherlands Twin Register (NTR) $\lambda=1.08$

f. Queensland Institute of Medical Research Berghofer adults (QIMR Berghofer adults) $\lambda=0.8$

g. Tracking Adolescents' Individual Lives Survey (TRAILS) $\lambda = .87$

h. Utrecht $\lambda = .99$

i. Genetics of Substance Dependence - European American (Yale Penn) $\lambda=1.02$

Figure S4a-l. Regional association plots showing signal around top SNPs

Regional plots showing the top independent SNPs (displayed as a violet dot at the top of the figure) in the discovery meta-analysis. The strength of the signal is displayed on the y-axis ($-\log_{10}$ p-value), and the chromosomal position is shown on the x-axis. The blue lines represent the recombination rate. The LD (r^2) of the SNPs within the region with the top signal is colour coded.

Abbreviations: *B* – beta (effect size); *SE* – standard error of beta; *N* – sample size; *EAF* –effect c

Note: In the BLTS (discovery) sample, and in the CADD and NTR2/RADAR (replication) samples the SNP rs 1574587 f

Note: rs1574587 is located at chromosome 16, base pair position 84453056, Allele 1=T, Allele 2 = C

e discovery samples and the replication samples.

allele frequency; INFO – imputation quality; $\lambda_{GC}SE$ – lambda corrected standard error; $\lambda_{GC}P$ –
ailed to meet the imputation quality threshold of $>.8$.

lambda corrected P-value;

Supplemental Information 1. Information about sample collection

ALSPAC: Avon Longitudinal Study of Parents and Children — United Kingdom

The Avon Longitudinal Study of Parents and Children (ALSPAC) is a prospective cohort study which recruited 14,541 pregnant women residing in Avon, United Kingdom, with expected dates of delivery between 1 April 1991 and 31 December 1992. Of these initial pregnancies, there was a total of 14,676 fetuses, resulting in 14,062 live births and 13,988 children who were alive at 1 year of age. Full details of study recruitment and methodology have been published previously¹. Detailed information on the mothers and their children has been collected from self-report questionnaires and attendance at clinics. Please note that the study website contains details of all the data that is available through a fully searchable data dictionary (<http://www.bris.ac.uk/alspac/researchers/data-access/data-dictionary/>). Ethical approval for the study was obtained from the ALSPAC Ethics and Law Committee and the Local Research Ethics Committees. Data on cannabis use for this project was measured in the ALSPAC offspring between 17 and 20 years of age and limited to unrelated individuals only. The answer categories were recoded as uncensored (coded as 0, ever used cannabis) versus censored (coded as 1, never used cannabis during their lifetime) observations. Individuals were also asked about frequency of cannabis use if they answered yes to ever having used cannabis. Cannabis data were available for 6,230 individuals. Both genotype and lifetime cannabis use data were available for 6,147 individuals.

BLTS: Brisbane Longitudinal Twin Study - Australia

Beginning in 1992, the Brisbane Longitudinal Twin Study (BLTS) consists of 3,561 individuals: 1,422 twin pairs and 717 additional siblings first enrolled at age 12 years and now aged 30 years and older (Gillespie, 2013). The sample is: (a) genetically informative (MZ and DZ twins, and often parents and siblings; genotyped for 610,000 common single nucleotide polymorphisms - SNPs); (b) large; (c) longitudinal with many participants have been assessed at 12, 14, 16 and 21 years of age; (d) well characterized for behavioral and brain-related outcomes; (e) rich in biological samples; and includes (f) a subgroup [n=969] who have undergone MRI scanning. As part of an ongoing US NIH/NIDA funded project beginning 2009, measures of lifetime cannabis use, abuse and dependence data are collected, along with diagnostic data for nicotine, alcohol, and other illicit substances, as well as pilot epidemiological data for ecstasy and methamphetamine use. The average age at interview is 25.65 yrs (SD=3.65, range=18-38yrs). Lifetime cannabis use was assessed by asking twins, "In your life, have you ever used cannabis (marijuana, pot, grass or hash)?" The answer categories were recoded as uncensored (coded as 0, if one ever used cannabis) versus censored (coded as 1, if one never used cannabis during the lifetime) observations. Age at initiation was assessed by the question "At what age did you first use cannabis?". The entire BLTS sample and 1,549 of their parents have GWAS data (Illumina 610k chip) (Medland et al., 2009) imputed on the GRCh37 assembly. The final sample included 721 individuals (314 males and 407 females) with both genotypic and age at cannabis initiation data.

CADD:

Data on cannabis use and DNAs were collected as part of two longitudinal centers based in Colorado and California, the Center on Antisocial Drug Dependence (CADD) and the Genetics of Antisocial Drug Dependence (GADD). Subjects from the centers included both clinical and community samples with up to three waves of data collection at approximately 5 year intervals. The original set of unrelated subjects from Derringer (2015) was augmented with additional family members. For these analyses, genotypes were available from 1806 individuals who were over-selected for adolescent behavioral disinhibition. 35.5% of the sample were females, and the mean age was 23.65 (4.36) years, with a range from 13-38 years. Lifetime cannabis use data were collected using a supplemental questionnaire appended to the CIDI-SAM, which asked participants to self report "Have you ever used _____?" (yes/no) for each of 14 substances (plus "other"), including cannabis. 81.9% of respondents reported ever using cannabis. If participants answered in the affirmative, they were asked to respond to questions about age at first use, age at regular use, typical pattern of use, and days used within the past six months; otherwise, participants were instructed to skip to questions about the next substance. If subjects had been assessed on more than one occasion, age of initiation was taken from the assessment when they first reported cannabis use. Genotyping was conducted using the Affymetrix 6 platform. Samples were excluded if their call rate was less than 95%, if they were one of 18 samples from the oldest cohort (as this was too few to be used as a reference cohort), or if they did not have phenotype data. After these exclusions, 541445 SNPs passed initial genotyping QC that removed SNPs with MAF <1%, or call rate <99%, or $p(\text{HWE}) < 1.00\text{E-}06$. Genotype calling used GeneChip Targeted Genotyping Analysis Software. FinnTwin: Finnish Twin Cohort (FinnTwin12 & FinnTwin16) - Finland

In FinnTwin12 (FT12), data on lifetime cannabis use were collected as part of a longitudinal study targeting all Finnish twin pairs born in 1983-1987 (Kaprio, Pulkkinen, Rose 2002). Four waves of data collection have been completed (at ages 12, 14, 17.5, and in early adulthood age range 21-25) (Kaprio, 2013). In wave 4, using a SSAGA interview we asked whether participants ever experimented with cannabis (no, yes) and if yes, at what age they first experimented with cannabis. They were also asked how many times they have used cannabis. Cannabis abuse and dependence were also assessed. Lifetime cannabis use data were available for 1346 FT12 subjects (25.3% (N=341) ever users). Both genotype and cannabis data were available for 929 FT12 subjects (26.6% (N=247) ever users). The mean age of cannabis use initiation among ever users was 17.8 (SD 2.2).

In FinnTwin16 (FT16), data on lifetime cannabis use were collected as part of a longitudinal study targeting all Finnish twin pairs born in 1975-1979 (Kaprio, Pulkkinen, Rose, 2002). Five waves of data collection have been completed (at ages 16, 17, 18.5, mean age 24, and mean age 34). In wave 4 we conducted SSAGA interviews from a subsample. In the SSAGA interview we asked whether participants ever experimented with cannabis (no, yes) and if yes, at what age they first experimented with cannabis. They were also asked how many times they have used cannabis. Cannabis abuse and dependence were also assessed. Lifetime cannabis use data were available for 602 FT16 subjects (34.2% (N=206) ever users). Both genotype and cannabis data were available for 100 FT16 subjects (36.0% (N=36) ever users). The mean age of cannabis use initiation among ever users was 19.9 (SD 3.0).

FinnTwin12 and FinnTwin16 samples were analyzed together. The answer categories were recoded as uncensored (coded as 0, if one ever used cannabis) versus censored (coded as 1, if one never used cannabis during the lifetime) observations. Both genotype and cannabis use data were available for altogether 1029 subjects (27.5% (N=283) ever users). The mean age of cannabis use initiation among ever users was 18.0 (SD 2.5).

HUVH: Hospital Universitari Vall d'Hebron – Barcelona - Spain

Data on lifetime cannabis use were collected as part of a GWAS study of persistent ADHD. Recruitment of participants was performed between 2004 and 2011 at the Department of Psychiatry of the Hospital Universitari Vall d'Hebron, Barcelona, Spain. Genotypes were available from 1039 unrelated Caucasian individuals. Age at initiation of lifetime cannabis use data was collected from 581 of them) and assessed by the Structured Clinical Interview for DSM-IV Axis I and Axis II Disorders (SCID-I and SCID-II). The average age at assessment was 28.7 years (SD = 12.5), 71% of participants were males. The study was approved by the ethics committee of the institution and informed consent was obtained from all subjects.

NTR1 and NTR2: Netherlands Twin Register — The Netherlands

Data on lifetime cannabis use were collected as part of a longitudinal study on health, personality and lifestyle in adolescent and adult twins and their relatives (i.e., their non-twin siblings, parents, spouses and children). Ten waves of data collection have been completed (in 1991, 1993, 1995, 1997, 2000, 2002, 2004 and 2009-2010, 2011-2012, and 2013-2014). Questions on cannabis use were administered 5 times: in 1993 (wave 2), 1995 (wave 3), , 2000 (wave 5), 2009-2010 (wave 8), and 2013-2014 (wave 10). In wave 2, 3, and 5 the participants were asked at what age they had experimented with cannabis for the first time and at what age they had regularly used cannabis. The answer categories were: 1=never, 2=11 years or younger, 3=12 years, 4=13 years, 5=14 years, 6=15 years, 7=16 years, 8=17 years, 9=18 years or older in wave 2 and 3, and 1=11 years or younger, 2=12-13 years, 3=14-15 years, 4=16-17 years, 5=18 years or older and never in wave 5. In wave 8 and 10 participants were asked whether they had ever experimented with cannabis (no, yes) and if yes, at what age they started. They were also asked whether they had ever used cannabis on a regular basis (no, yes) and if yes, at what age. For the NTR1 sample, we limited the sample to data from wave 8, as in this wave age at initiation was collected based on an open question (see above) and wave 10 was not available yet during the discovery phase of our study. For NTR2 we used data from individuals that were no family members of the individuals in the NTR1 sample. For NTR2 we used the responses from wave 10, and when missing we also used the responses to waves 5, 3, and 2 (in this order). The answer categories were recoded to uncensored observations (coded as 0, if one ever used cannabis) versus censored observations (coded as 1, if one never used cannabis). Both genotype and age at initiation of cannabis use data were available for 5,148 subjects for NTR1 and for 1,740 individuals for NTR2.

QIMR: Queensland Institute of Medical Research Berghofer adults — Australia

Data from Australian adults were collected in twin family studies conducted at the QIMR Berghofer Medical Research Institute. Data on cannabis use were obtained from: 1) a series of studies conducted collaboratively by Nick Martin and Andrew Heath between 2001 and 2006 (Pergadia et al., 2009; Saccone et al., 2007; Distel et al., 2008), and 2) a study conducted between 1996 and 2000 of 6233 twin individuals from the young adult cohort (born between 1964 and 1971) (see Nelson et al. 2002; Knopik et al. 2004). In both studies individuals participated in semi-structured telephone interviews primarily focussed at psychiatric disorders. The interview was an adaptation of the SSAGA (Semi-Structured Assessment for the Genetics of Alcoholism). As part of this interview individuals were asked whether they had ever used cannabis and at what age they first used cannabis (with the question: “How old were you when you first used...?”). In case individuals participated in both studies, data from the last assessment were included.

The genotypic data are derived from multiple waves of genotyping. DNA samples were collected in accordance with standard protocols and submitted to different genotype centres using different Illumina SNP platforms (317 single, 370 single, 370 duo, 670 quad, 610 quad) (see Medland et al., 2009). Phenotypic and genotypic data collections were approved by the QIMR Human Research Ethics Committee and informed consent was obtained from all participants.

The final sample included 6,758 individuals with both genotype and phenotype data (NB. One twin per MZ twin pair was deleted).

RADAR: Research on Adolescent Development and Relationships – The Netherlands

The RADAR study (Research on Adolescent Development and Relationships) is longitudinal research project in the Netherlands and focuses on the development of interpersonal relationships, personality, and psychopathology, in a sample of adolescents and their families that were followed from approximately ages 13 to 19. Currently, there are 7 waves available (collected between 2006 and 2013), but the study is still ongoing. The RADAR study has a focus on delinquency development, therefore adolescents at risk for externalizing behavior were oversampled, which was determined by a having a T-score > 60 on the externalizing scale of the Teacher's Report Form at age 12 (TRF; Achenbach, 1991; Verhulst, van der Ende, & Koot, 1997). In total, 497 adolescents were included in the study, of which 206 (41.45%) were at high risk for externalizing behavior (for more information on the sample see Creemers et al., 2015). The study was approved by the medical ethical committee of Utrecht University. Families received 100 Euros for each home visit. The data on lifetime cannabis use were collected every year as part of home assessments, during which research assistants visited the adolescents and their families (wave 1-7). Using self-report questionnaires, adolescents were asked to indicate how often they had used hash or weed in the past 12 months. Answer categories were 0 times, 1 time, 2 times, 3 times, 4 times, 5 times, 6 times, 7 times, 8 times, 9 times, 10 times, 11-19 times, 20-39 times, 40 times or more. Additionally, adolescents were asked how old they were when they had used weed or hash for the first time, but only in the last wave (wave 7). For the present analyses, age at onset of cannabis use was based on the response to wave 7, but if missing it was calculated based on all annual assessments.

In wave 5, 416 adolescents provided genotype data. For the current study, valid genotype and phenotype data were available for 342 adolescents. The mean age at wave 7 was 19.5 (SD = 0.8, range = 13–22).

Saguenay Youth Study

The Saguenay Youth Study (SYS) is a population-based study of adolescents and their middle-aged parents¹. It is aimed at investigating the etiology, early stages and trans-generational trajectories of common cardio-metabolic and brain diseases. The SYS was designed as a two-generational cohort; it includes 1,029 adolescents and their 962 parents. The cohort was recruited via 12- to 18-year old adolescents attending high schools in the Saguenay Lac-Saint-Jean region of Quebec (Canada). Half of the adolescents were exposed prenatally to maternal cigarette smoking. The cohort is family-based (n=481 families), including only adolescents who have one or more siblings of similar age (i.e., 12 to 18 years) and both biological parents of the French-Canadian origin born in the region. The data collection occurred in two waves. Wave 1 (2003-2012) involved the recruitment and complete assessment of all 1,028 adolescents, as well as a partial ('soft') assessment of 962 parents. Wave 2 (2012-2015) involved the complete assessment of a subset of the parents (n=664). In Wave 2, parents answered a series of questions about their drug use; this questionnaire was based on the European School Survey Project on Alcohol and Other Drugs (<http://www.espad.org/>). The GWAS was based on answering (Yes/No) the following question: "Have you ever used marijuana (grass, pot) or hashish (hash, hash oil)?" with the following answer categories: 1=11 or less 2= 12 3=13 4=14 5=15 6=16 7=17 8=18 and more 9= prefer to not answer. Of the total sample (N=593), 310 individuals did not initiate cannabis use, 184 individuals initiated cannabis use at an age between 12 and 17 years and 99 individuals said they did so at 18 years of later. Given that the average age at initiation is around 15.4 (youth), 16.5 (young adults) and 18.8 (adults) (www.ccsa.ca/), the age at initiation for this last group is set on 18 years old in order to allow us to use the full sample and so, to maximize the power to replicate the results. We note that re-running the analysis by excluding this group did not change the results and the conclusions of the replication stage.

TRAILS: TRacking Adolescents' Individual Lives Survey — The Netherlands.

Data on lifetime cannabis use were collected as part of a Dutch longitudinal study on the development of (mental) health in adolescence and young adulthood. Data on lifetime cannabis use were collected at the fourth wave, in 2008-2010, when the sample was 18-20 years old. The participants were asked if and how often they had used cannabis during (1) their lives, (2) the last year, and (3) the last month; and how old they were when they used cannabis for the first time. Both genotype and data on lifetime cannabis use and age at initiation were available for 1249 subjects.

Utrecht: Utrecht Cannabis Cohort (CannabisQuest) –The Netherlands

Participants were recruited using a project website launched in 2006 targeted at Dutch young adults and adolescents from 18 to 25 years (www.cannabisquest.nl) (Schubart et al., 2010). Strategies to generate traffic on the project website included collaboration with over a hundred colleges, universities, and youth centres, as well as the use of online commercial advertisement products (i.e. banners and text links) (Schubart et al., 2010). The chance to win an Apple iPod™ or a Nintendo Wii™ was used as an incentive. Double entries were prevented by exclusion of subjects with an identical e-mail address, surname, and date of birth. Anonymous submission of data was not possible. The online assessment included verification questions to protect against random answers, and participants failing to correctly complete the verification questions were subsequently excluded. From the online data (N = 17,698), 1259 participants were included for subsequent genetic assessment in two waves. First, in order to increase power for gene × environment interactions (Boks et al., 2007), we prioritized a sample of 719 participants who belonged to the top or bottom quintile of total scores of psychotic experiences as measured by the Community Assessment of Psychic Experiences (CAPE) score (see below) that were either cannabis naïve (i.e. a lifetime cannabis exposure frequency less than 6 times) or were cannabis users (i.e. current expenditure for personal cannabis use exceeded 3€ weekly). Second, an unselected sample of 540 individuals was included. As ascertained with the validated Dutch version of either the Structured Clinical Interview (SCID) (First et al., 1997) or the MINI International Neuropsychiatric Interview (Sheehan et al., 1998), healthy controls had no history of any psychotic disorder. The possible concomitant use of recreational drugs was assessed with the substance abuse module of the Composite International Diagnostic Interview (Compton, 1993). Participants provided a urine sample to screen for the presence of recreational drugs in order to verify recent self-reported cannabis use. The study was approved by the Ethical Review Board of the University Medical Center Utrecht and all participants gave written informed consent. For a total of 1173 participants data on age at initiation of cannabis use and genotypes were available.

Yale Penn EA: Genetics of Substance Dependence - United States

Our sample included a total of 2,379 European American (EA) subjects from a cohort of small nuclear families and unrelated individuals originally collected to study the genetics of drug (opioid or cocaine) or alcohol dependence (Gelernter et al., 2014). Subjects gave written informed consent as approved by the institutional review board at each site, and certificates of confidentiality were obtained from NIDA and NIAAA. Yale/Penn subjects were administered the Semi-Structured Assessment for Drug Dependence and Alcoholism (SSADDA) (Pierucci-Lagha et al, 2005) to derive DSM-V diagnoses of lifetime cannabis dependence and other major psychiatric traits. Lifetime cannabis use was assessed by the following question: “Have you ever used marijuana to feel good or high, or to feel more active or alert.” Age at first use, as well as a measure of frequency of during the period in the subject’s life in which they used the drug most heavily, was also assessed. A total of 2,188 subjects for which both age at initiation of cannabis use and genotypes were available were used in this study.

Heritability study

Subjects: The sample for estimating the heritability for age at first cannabis use consisted of 8,055 twin pairs from three samples: the NTR sample comprising 3,798 twin pairs (Willemsen et al., 2013), the QIMR sample comprising 3,251 twin pairs (Heath et al., 2011; Knopik et al., 2004), and the BLTS sample comprising 1,006 twin pairs (Gillespie et al., 2013). The prevalence of lifetime cannabis use was 24%, 57%, and 51% in the NTR, QIMR, and BLTS samples respectively. Among ever or lifetime cannabis users, the percentage early initiators (before the age of 18) was 56%, 36% and 51% respectively.

Measures: To investigate the heritability of age at first cannabis use, this trait was considered to have an underlying, continuous liability. A threshold liability model was then used to divide age at first cannabis use into four ordinal categories: users who initiated cannabis before age 18, initiation between ages 18 to 20, initiation after age 20, and never users.

Genetic models: We fitted and compared three models to determine the relationship between risk of cannabis initiation *per se* and the age at first use. The single liability dimension model (SLD) postulates that the liability to cannabis initiation and the age at first cannabis use fall along the same dimension of risk or liability. In contrast, the independent liability dimension (ILD) model predicts that these liabilities are independent of one another. Finally, the combined model (CM) postulates the existence of separate dimensions, while allowing for the possibility that these dimensions are correlated. For more details, see Vink et al. (2005).

Model fitting: Age at first cannabis use in the first twin was cross-classified with age at first cannabis use in the second twin, resulting in 4x4 contingency tables for each of the five zygosity groups: monozygotic males, dizygotic males, monozygotic females, dizygotic females and dizygotic opposite sex twins. The three models were then fitted to the five contingency tables using maximum likelihood in the structural equation modelling package

MX (Neale et al., 2006), and the goodness-of-fit of the (nested) models was assessed using likelihood-ratio chi-square statistics. For the model that gave the best description of the data, the twin correlations in liability were expressed as a function of genetic and environmental parameters based on the classical twin design (Neale and Cardon, 1992). Sources of variation that were considered in modelling were additive genetic variation (A), shared environmental variation (C) and unique environmental variation that is not shared by twin pairs (E).

Effective sample size for SNP-based heritability estimation

Estimates of heritability from LD score regression and the So et al. method depend on the relationship between sample size, effect size, and corresponding test statistic. Using the Cox proportional hazards model and applying genomic control both affect that relationship in the current analysis. Therefore we approximate the effective sample size (i.e. the sample size with the intended statistical behavior for heritability analysis) of the current GWAS. For simplicity we motivate the derivation of the effective sample size calculation using LD score regression and apply the same calculation with the So et al. method.

First, we note that the statistical power of the Cox proportional-hazards regression model is directly proportional to the number of observed events rather than the number of individuals in study (Schoenfeld, 1983; Hsieh, 2000). As derived by Hsieh, the noncentrality parameter for the chi-square test of the regression coefficient β is:

$$D\sigma^2\beta^2$$

where D is the number of events and σ^2 is the variance of the regression covariate. By comparison, LD score regression assumes a chi square statistic with noncentrality parameter

$$N\beta^2$$

where the effect size beta is defined assuming a standardized genotype and standardized phenotype. Using a standardized genotype implies $\sigma^2 = 1$, leaving non-centrality parameter $D\beta^2$, confirming that the number of events D rather than the number of individuals N is the appropriate effective sample size in the Cox proportional hazards model.

Second, we note that the use of genomic control in each cohort will proportionately reduce the chi-square statistic. As derived by Bulik-Sullivan et al. (2015), the use of genomic control modifies the relationship between heritability and expected chi-square statistic to replace the sample size with

$$\frac{1}{N} \sum_j \sum_k \frac{N_j N_k}{\sqrt{\lambda_j \lambda_k}}$$

where λ_j is the genomic control factor and N_j is the sample size for each study j and N is to total sample size.

Putting this together with the adjustment for power in the Cox proportional hazard model gives a final effective sample size of:

$$N_{effective} = \frac{1}{D} \sum_j \sum_k \frac{D_j D_k}{\sqrt{\lambda_j \lambda_k}}$$

D is the number of uncensored observations (i.e. the number of individuals with observed cannabis initiation).

Note that neither of these adjustments account for the use of family data analyzed allowing correlated standard errors, which will further reduce the effective sample size. As such, the effective sample size described above is likely to be too large, and thus our estimates of heritability will be deflated proportional to the amount of relatedness in the analyzed cohorts.

GENOME-WIDE ASSOCIATION META-ANALYSIS OF AGE AT FIRST CANNABIS USE – REPLICATION ANALYSES

We performed a GWAS meta-analysis of age at first cannabis use in a discovery sample of 24,953 individuals from nine cohorts from Europe, Australia, and the United States. The top findings obtained in the single nucleotide polymorphisms (SNP) and gene-based analyses were tested for replication.

MATERIALS AND METHODS

The replication sample comprised of 3,735 individuals with a mean age ranging from 24 to 49.4 years (Table 1S5). Females represented 53.9% of the sample, and 45.3% of the observations were uncensored (see Supplementary Table S1 for more details on the samples).

Table 1S5: Descriptive information on the participating replication cohorts.

Cohort	N	% Females	%Uncensored Observations	Mean age (SD)	Mean age at first use (sd) (in users)	Number of SNPs
CADD	1060	40.18	78	24.06 (4.2)	14.2 (3.16)	8*
NTR2**	1740	63.7	22.2	35.0 (14.6)	18.0 (4.0)	8*
RADAR**	342	44.7	57.0	19.5 (0.8)	15.9 (1.7)	8*
SYS	593	55.3	47.7	49.4 (5.1)	16.2 (1.7)	8*

*CADD - the Center on Antisocial Drug Dependence; NTR – the Netherlands Twin Register sample 2; RADAR: Research on Adolescent Development and Relationships; N = sample size, % uncensored observations (i.e., individuals who have initiated cannabis use). Mean age: age when completing survey or interview. Mean age at first use: mean age at first cannabis use * In the replication samples only the top 8 independent SNPs were tested. ** The NTR2 and the RADAR samples were combined and the analysis was performed in this combined sample.*

Phenotyping

For details on phenotyping in the participating samples we refer to the main manuscript, and to Supplementary File S1 for information on the exact phrasing of the question used to collect the data by each replication cohort.

Genotyping

Details on genotyping in the GWAS participating cohorts are included in the main manuscript. For information on the extensive quality control (QC) performed by each participating cohort we refer to the Supplementary Table S2.

Imputation

All participating cohorts performed genotype imputation using the 1000 Genomes Phase 1 March 2012 release as reference (40) (see Supplementary Table S2 for further imputation details).

Quality checks prior to meta-analysis

The same quality checks performed in the discovery sample (see main manuscript for details) were applied in the replication cohorts.

Power analysis

We evaluated the power to detect a significant association in the replication sample using the R library "powerSurvEpi".

Statistical analysis of individual samples, meta-analysis and gene-based tests of association

We implemented the same procedures and options in the replication phase as in the discovery meta-analysis. Statistical analyses were performed on the Lisa Genetic Cluster Computer (<http://www.geneticcluster.org>).

Polygenic score analysis

Polygenic score analyses were carried out to determine if age at first cannabis use could be predicted in the replication samples. Results from the GWAS discovery meta-analysis were used to create polygenic scores in an independent sample from the Netherlands (the combined sample of NTR2-RADAR (see Table 1, and Supplementary Tables S1, S2, and Supplemental File S1). We used LDpred (55) to take into account LD among the SNPs when creating the polygenic scores. The polygenic scores were generated by calculating the mean causal effect size of each marker using the SNP effect sizes from the GWAS discovery meta-analysis and the LD structure from the European populations in the 1000 Genomes Phase I reference set.

Polygenic scores were computed based on the genome-wide meta-analysis results from which we selected only genotyped SNPs (i.e. non-imputed) present in at least 7 of the discovery cohorts. The final number of SNPs included was 376,819. Polygenic scores were calculated for several expected fractions of causal genetic markers to optimize prediction accuracy (0.1%, 1%, 10%, and 100%). The scores were transformed into z-values before analysis. We then tested if the computed polygenic scores predicted age at first cannabis use in the independent target cohort using a Cox proportional hazards regression in R (as applied in the main analyses). Age at first cannabis use (or age at the last survey for censored observations) was regressed on the polygenic scores. Sex, birth cohort, and three ancestry-

informative genetic PCs were included as covariates in the model. To account for family relatedness we used the ‘cluster’ option implemented in the survival R-package.

RESULTS

Power analysis

Table 2-S5 displays the results of our power analysis.

Beta	Hazard Ratio	MAF	alpha	Power
0.09	1.094174	0.14	0.005	0.07
-0.06	0.941765	0.77	0.005	0.04
0.07	1.072508	0.46	0.005	0.09
-0.07	0.932394	0.27	0.005	0.07
0.07	1.072508	0.8	0.005	0.05
-0.11	0.895834	0.07	0.005	0.04
0.06	1.061837	0.73	0.005	0.04
-0.06	0.941765	0.74	0.005	0.04

The power to replicate the top 8 SNPs was low, ranging from 0.04 to 0.10.

GWAS meta-analysis

In the independent replication samples, none of the 8 tested SNPs replicated (see Table 3-S5 for details). Note that the top SNP remained significant in the combined discovery and replication meta-analysis ($P=8.7E-09$).

Table 3-S5. Results for the top 8 independent SNPs in the meta-analysis of the discovery samples (present in at least one replication sample), and results of the meta-analysis of combined discovery and replication samples. SNPs are displayed when not in linkage

disequilibrium ($R^2 < 0.1$). For SNPs with $R^2 \geq 0.1$ only the most significant SNP is shown in the top 8.

* Direction per sample: allele A1 increases (+) or decreases (-) liability for cannabis use, or sample did not contribute to this SNP because it did not pass the post-imputation quality control (?). Order of samples in the replication meta-analysis: CADD, NTR2/RADAR, SYS. Sample information can be found in Table 1-S5.

Chr = Chromosome; BP (hg19) = location in base pairs in human genome version 19, A1 = allele 1, A2 = allele 2, Freq A1 = Frequency of allele 1, s.e. = standard error, P = p-value.

§The combined sample contains the discovery samples and the CADD, NTR2/Radar and SYS replication samples.

Gene-based tests of association

The *ATP2C2* gene did not reach significance in the meta-analysis of the replication samples ($P=0.47$).

Polygenic score analysis

None of the polygenic scores for age at first cannabis use explained significant proportions of variance in age at first use in the independent target sample NTR2-RADAR; all polygenic scores based on different expected fractions of causal markers yielded p-values > 0.10 .
